

Python Objects and Classes

Estimated time needed: 10 minutes

Objectives

In this reading, you will learn about:

- Fundamental concepts of Python objects and classes.
- · Structure of classes and object code.
- · Real-world examples related to objects and classes.

Introduction to classes and object

Python is an object-oriented programming (OOP) language that uses a paradigm centered around objects and classes.

Let's look at these fundamental concepts.

Classes

A class is a blueprint or template for creating objects. It defines the structure and behavior that its objects will have.

Think of a class as a cookie cutter and objects as the cookies cut from that template.

In Python, you can create classes using the class keyword.

Creating classes

When you create a class, you specify the attributes(data) and methods (functions) that objects of that class will have.

Attributes are defined as variables within the class, and methods are defined as functions.

For example, you can design a "Car" class with attributes such as "color" and "speed," along with methods like "accelerate."

Objects

An *object* is a fundamental unit in Python that represents a real-world entity or concept. Objects can be tangible (like a car) or abstract (like a student's grade).

Every object has two main characteristics:

State

The attributes or data that describe the object. For your "Car" object, this might include attributes like "color", "speed", and "fuel level".

Behavior

The actions or methods that the object can perform. In Python, methods are functions that belong to objects and can change the object's state or perform specific operations.

Instantiating objects

- Once you've defined a class, you can create individual objects (instances) based on that class.
- Each object is independent and has its own set of attributes and methods.
- To create an object, you use the class name followed by parentheses, so: "my_car = Car()"

Interacting with objects

You interact with objects by calling their methods or accessing their attributes using dot notation.

For example, if you have a Car object named my_car, you can set its color with my_car.color = "blue" and accelerate it with my_car.accelerate() if there's an accelerate method defined in the class.

Structure of classes and object code

Please don't directly copy and use this code because it is a template for explanation and not for specific results.

Class declaration (class ClassName)

- The class keyword is used to declare a class in Python.
- $\bullet \ \ {\tt ClassName} \ is the name of the class, typically following Camel Case naming conventions.$

about:blank 1/6

class ClassName:

Class attributes (class_attribute = value)

- Class attributes are variables shared among all class instances (objects).
- They are defined within the class but outside of any methods.

```
class ClassName:
    # Class attributes (shared by all instances)
    class_attribute = value
```

Constructor method (def init(self, attribute1, attribute2, ...):)

- The __init__ method is a special method known as the constructor.
- It initializes the instance attributes (also called instance variables) when an object is created.
- The self parameter is the first parameter of the constructor, referring to the instance being created.
- attribute1, attribute2, and so on are parameters passed to the constructor when creating an object.
- Inside the constructor, self.attribute1, self.attribute2, and so on are used to assign values to instance attributes.

Instance attributes (self.attribute1 = attribute1)

- Instance attributes are variables that store data specific to each class instance.
- They are initialized within the <u>__init__</u> method using the self keyword followed by the attribute name.
- These attributes hold unique data for each object created from the class.

```
class ClassName:
    # Class attributes (shared by all instances)
    class_attribute = value
    # Constructor method (initialize instance attributes)
    def __init__(self, attribute1, attribute2, ...):
        self.attribute1 = attribute1
        self.attribute2 = attribute2
        # ...
```

Instance methods (def method1(self, parameter1, parameter2, ...):)

- Instance methods are functions defined within the class.
- They operate on the instance's data (instance attributes) and can perform actions specific to instances.
- The self parameter is required in instance methods, allowing them to access instance attributes and call other methods within the class.

about:blank

2/6

```
class ClassName:
    # Class attributes (shared by all instances)
    class_attribute = value
    # Constructor method (initialize instance attributes)
    def __init__(self, attribute1, attribute2, ...):
        self.attribute1 = attribute1
        self.attribute2 = attribute2
        # ...
# Instance methods (functions)
    def method1(self, parameter1, parameter2, ...):
        # Method logic
        pass
```

Using the same steps you can define multiple instance methods.

```
class ClassName:
    # Class attributes (shared by all instances)
    class_attribute = value
    # Constructor method (initialize instance attributes)
    def __init__(self, attribute1, attribute2, ...):
        self.attribute1 = attribute1
        self.attribute2 = attribute2
        # ...
    # Instance methods (functions)
    def method1(self, parameter1, parameter2, ...):
        # Method logic
        pass
    def method2(self, parameter1, parameter2, ...):
        # Method logic
        pass
```

Note: Now, you have successfully created a dummy class.

Creating objects (Instances)

- To create objects (instances) of the class, you call the class like a function and provide arguments the constructor requires.
- Each object is a distinct instance of the class, with its own instance attributes and the ability to call methods defined in the class.

```
# Create objects (instances) of the class
object1 = ClassName(arg1, arg2, ...)
object2 = ClassName(arg1, arg2, ...)
```

Calling methods on objects

- In this section, you will call methods on objects, specifically object1 and object2.
- The methods method1 and method2 are defined in the ClassName class, and you're calling them on object1 and object2 respectively.
- You pass values param1_value and param2_value as arguments to these methods. These arguments are used within the method's logic.

Method 1: Using dot notation

- This is the most straightforward way to call an object's method. In this, use the dot notation (object.method()) to invoke the method on the object directly.
- For example, result1 = object1.method1(param1_value, param2_value, ...) calls method1 on object1.

```
# Calling methods on objects
# Method 1: Using dot notation
result1 = object1.method1(param1_value, param2_value, ...)
result2 = object2.method2(param1_value, param2_value, ...)
```

about:blank 3/6

Method 2: Assigning object methods to variables

- Here's an alternative way to call an object's method by assigning the method reference to a variable.
- method_reference = object1.method1 assigns the method method1 of object1 to the variable method reference.
- Later, call the method using the variable like this: result3 = method_reference(param1_value, param2_value, ...).

```
# Method 2: Assigning object methods to variables
method_reference = object1.method1 # Assign the method to a variable
result3 = method_reference(param1_value, param2_value, ...)
```

Accessing object attributes

- Here, you are accessing an object's attribute using dot notation.
- attribute_value = object1.attribute1 retrieves the value of the attribute attribute1 from object1 and assigns it to the variable attribute_value.

```
# Accessing object attributes
attribute_value = object1.attribute1  # Access the attribute using dot notation
```

Modifying object attributes

- You will modify an object's attribute using dot notation.
- object1.attribute2 = new_value sets the attribute attribute2 of object1 to the new value new_value.

```
# Modifying object attributes
object1.attribute2 = new_value  # Change the value of an attribute using dot notation
```

Accessing class attributes (shared by all instances)

- Finally, access a class attribute shared by all class instances.
- class_attr_value = ClassName.class_attribute accesses the class attribute class_attribute from the ClassName class and assigns its value to the variable. class_attr_value.

```
# Accessing class attributes (shared by all instances)
class_attr_value = ClassName.class_attribute
```

Real-world example

Let's write a python program that simulates a simple car class, allowing you to create car instances, accelerate them, and display their current speeds.

- 1. Let's start by defining a Car class that includes the following attributes and methods:
- Class attribute max_speed, which is set to 120 km/h.
- Constructor method __init__ that takes parameters for the car's make, model, color, and an optional speed (defaulting to 0). This method initializes instance attributes for make, model, color, and speed.
- Method accelerate(self, acceleration) that allows the car to accelerate. If the acceleration does not exceed the max_speed, update the car's speed attribute. Otherwise, set the speed to the max_speed.
- Method get_speed(self) that returns the current speed of the car.

```
class Car:
    # Class attribute (shared by all instances)
    max_speed = 120  # Maximum speed in km/h
    # Constructor method (initialize instance attributes)
    def __init__(self, make, model, color, speed=0):
        self.make = make
        self.model = model
        self.color = color
        self.speed = speed  # Initial speed is set to 0
    # Method for accelerating the car
    def accelerate(self, acceleration):
        if self.speed + acceleration <= Car.max_speed:
            self.speed = Car.max_speed
    # Method to get the current speed of the car
    def get_speed(self):
        return self.speed</pre>
```

2. Now, you will instantiate two objects of the Car class, each with the following characteristics:

- carl: Make = "Toyota", Model = "Camry", Color = "Blue"
- car2: Make = "Honda", Model = "Civic", Color = "Red"

```
# Create objects (instances) of the Car class
car1 = Car("Toyota", "Camry", "Blue")
car2 = Car("Honda", "Civic", "Red")
```

3. Using the accelerate method, you will increase the speed of car1 by 30 km/h and car2 by 20 km/h.

```
# Accelerate the cars
car1.accelerate(30)
car2.accelerate(20)
```

4. Lastly, you will display the current speed of each car by utilizing the get_speed method.

```
# Print the current speeds of the cars
print(f"{car1.make} {car1.model} is currently at {car1.get_speed()} km/h.")
print(f"{car2.make} {car2.model} is currently at {car2.get_speed()} km/h.")
```

Next steps

In conclusion, this reading provides a fundamental understanding of objects and classes in Python, essential concepts in object-oriented programming. Classes serve as blueprints for creating objects, encapsulating data attributes and methods. Objects represent real-world entities and possess their unique state and behavior. The structured code example presented in the reading outlines the key elements of a class, including class attributes, the constructor method for initializing instance attributes, and instance methods for defining object-specific functionality.

In the upcoming laboratory session, you can apply the concepts of objects and classes to gain hands-on experience.
